## Abstract

Cross-national analyses can illuminate global patternings of national-level outcomes. But since nations are connected in various ways, such as via spatial proximity and shared cultural ancestry, cross-national analyses often violate assumptions of non-independence, inflating false positive rates. Here, we show that, despite being recognised as an important statistical pitfall for over 200 years, cross-national research in economics and psychology still does not sufficiently account for non-independence. In a review of the 100 highest-cited cross-national studies of economic development and values, we find that controls for non-independence are rare and have remained so over the past 30 years. When studies do include controls for non-independence, our simulations suggest that commonly used methods continue to produce false positives. In reanalyses of twelve cross-national relationships, we show that half are no longer significant after controlling for non-independence using global proximity matrices. We urge social scientists to sufficiently control for non-independence in cross-national research.

## The non-independence of nations and why it matters

Nations are perhaps the single most important population unit structuring modern human life. The nation in which someone is born has a large effect on what they can expect out of life, including their income level<sup>1</sup>, life expectancy<sup>2</sup>, mental health<sup>3</sup>, subjective well-being<sup>4</sup>, and educational attainment<sup>5</sup>. Nations are also among the most important determinants of human cultural variation, with greater cultural similarity within than outside national borders<sup>6</sup>.

Given the importance of nations for structuring human behaviour, there is justifiably huge interest in statistical analyses that attempt to predict variation in national-level outcomes of all kinds. At the time of writing, a search in Web of Science for the terms “cross-national”, “cross-cultural”, or “cross-country” in titles and abstracts returned 80,000 unique hits. The standard practice for cross-national analyses is to conduct bivariate correlations or multiple regressions with individual data points representing different nations. Such analyses widen the scope of social science beyond Western populations<sup>7,8</sup> and have been used to study, among other topics, the causes of variation in the economic wealth of nations<sup>9–12</sup>, global patterings of cultural norms and values<sup>13–16</sup>, and the universality and diversity of human behaviour and psychology around the world<sup>17–20</sup>.

However, cross-national analyses are complicated by the fact that nations are not statistically independent data points. Unlike independent random samples from a population, nations are related to one another in a number of ways. First, nations that are closer to one another tend to be more similar than distant nations. This phenomenon is known as spatial non-independence<sup>21</sup>, and it occurs because nations in close spatial proximity share characteristics due to local cultural diffusion of ideas<sup>22</sup> and regional variation in climate and environment<sup>21</sup>. For example, the neighbouring African nations Zambia and Tanzania have similar levels of terrain ruggedness, which has been used to partially explain their similar levels of economic development<sup>23</sup>. This pattern conforms to

Tobler’s first law of geography: “everything is related to everything else, but near things are more related than distant things”<sup>24</sup> (p. 236).

Second, nations with shared cultural ancestry tend to be more similar than culturally unrelated nations. This is known as cultural phylogenetic non-independence<sup>25–27</sup>, and occurs because related nations share cultural traits inherited via descent from a common ancestor. Shared cultural ancestry can result in a form of pseudoreplication, whereby multiple instances of the same trait across nations are merely duplicates of the ancestral original. For example, despite being separated by over 1500 kilometres of ocean, the related island nations Tonga and Tuvalu express similar languages and customs due to cultural inheritance from a shared ancestor deep in the evolutionary history of Polynesian societies. More recently, shared ancestry is also crucial in explaining cultural similarities between colonial settlements and their colonisers (e.g. Argentina and Spain).

Spatial and cultural phylogenetic non-independence between nations make cross-national inference challenging. A fundamental assumption of regression analysis is that model residuals should be independently and identically distributed<sup>28</sup>. But without accounting for spatial or cultural non-independence between nations, model residuals can show structure that remains unaccounted for, violating this assumption. Treating nations as independent can thus inflate false positive rates<sup>29</sup>, producing spurious “direct” relationships between variables that in fact only indirectly covary due to spatial or cultural connections<sup>30</sup> (see Supplementary Figure S1 for an example causal model).

Non-independence between data points is widely acknowledged in fields that routinely deal with spatially or culturally structured data. In ecology and sociology, studies with regional-level data use a variety of autoregressive models designed to account for spatial patternings<sup>31,32</sup>. In anthropology, researchers have recognised cultural non-independence as an important statistical pitfall for over 200 years, with issues of cultural pseudoreplication being identified in early comparative studies of marriage practices across societies<sup>25</sup>. More

recently, the Standard Cross-Cultural Sample of 186 cultures was compiled to minimise the confounding effects of non-independence in comparisons of traditional societies<sup>33</sup>, though spatial and cultural dependencies are difficult to remove entirely<sup>34,35</sup>. Anthropologists also borrow phylogenetic comparative methods from evolutionary biology, such as phylogenetic least squares regression<sup>36</sup>, when comparing traditional societies, treating culturally related societies in the same way as biologists treat genetically related species (e.g.<sup>37,38</sup>).

At the national level, recent reanalyses have revealed that several cross-national relationships reported in economics and psychology do not hold when controlling for non-independence between nations. One study replicated 25 analyses of “persistence” in economics, in which modern national outcomes are regressed against historical characteristics of those nations, and found that over half of the relationships were attenuated when controlling for spatial non-independence<sup>39</sup>. Another replication study found that many of the widely publicised relationships between national-level pathogen prevalence and political institutions and attitudes fail to hold when controlling for various kinds of non-independence<sup>40</sup>. These reanalyses, and others<sup>41–43</sup>, raise the question: how widespread a concern is non-independence in studies of national-level outcomes?

To address this question, we consider national-level variables of general interest across the social sciences: economic development and cultural values. These variables are frequently included as both outcomes and predictors in cross-national studies in economics and psychology<sup>9–16</sup>. First, we show that economic development and cultural values are spatially and culturally non-independent across nations, emphasising the need to control for non-independence. Second, we systematically review the 100 highest-cited cross-national studies of economic development and cultural values and estimate the proportion of cross-national analyses within these articles that account for non-independence between nations. Third, we run simulations to determine whether common methods of dealing with non-independence in the literature sufficiently reduce false positive rates. Fourth, we

reanalyse twelve previous cross-national analyses of economic development and cultural values from our systematic review, incorporating global geographic and linguistic proximity matrices to correctly control for spatial and cultural non-independence.

## Results

### **National-level economic development and cultural values are spatially and culturally non-independent**

In order to motivate our research question, it is important to first show that economic development and cultural values are indeed spatially and culturally non-independent around the world. To this end, we used Bayesian multilevel models to simultaneously estimate geographic and cultural phylogenetic signal for the Human Development Index<sup>44</sup> and two dimensions of cultural values from the World Values Survey, traditional vs. secular values and survival vs. self-expression values<sup>16</sup>. For all three of these variables, we found that a substantial proportion of national-level variation was explained by spatial proximity and shared cultural ancestry between nations (Figure 1). In our models, shared cultural ancestry explained over half of the national-level variation in economic development and cultural values, with spatial proximity explaining most of the remaining national-level variance. Bayes Factors indicated strong evidence that these estimates of geographic and cultural phylogenetic signal differed from zero, aside from the geographic signal for survival values, for which the evidence was equivocal (see Supplementary Results). These findings emphasise the need to account for spatial and cultural phylogenetic non-independence in cross-national analyses of economic development and cultural values.

### **Previous cross-national analyses have not sufficiently accounted for non-independence**

Since economic development and cultural values show evidence of geographic and cultural phylogenetic signal, have cross-national analyses sufficiently accounted for this

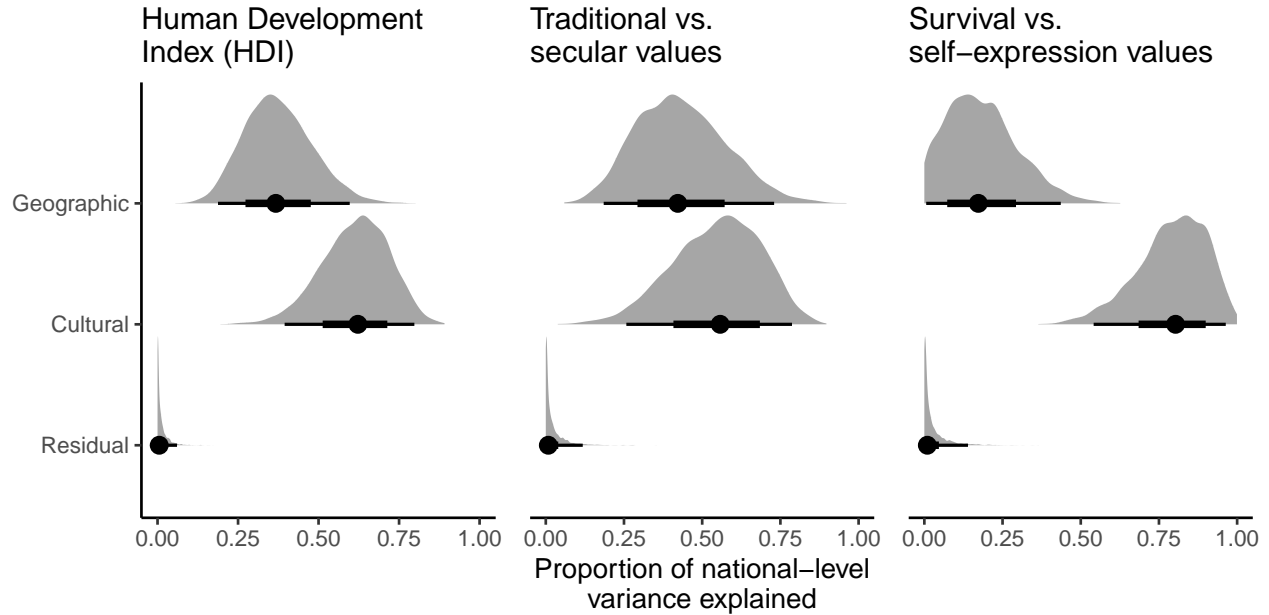

Figure 1. Posterior estimates of geographic and cultural phylogenetic signal for the Human Development Index and Inglehart’s traditional and survival values. Geographic and cultural phylogenetic signal are operationalised as the proportion of national-level variance explained by geographic and linguistic proximity matrices. Grey ridges are full posterior distributions, points are posterior median values, and lines are 50% and 95% credible intervals.

non-independence? To assess this, we systematically searched the published literature for articles that combined the search terms “economic development” or “values” with the search terms “cross-national”, “cross-cultural”, or “cross-country”. We removed articles that did not report original research, were not relevant to economic development or cultural values, or did not report at least one cross-national analysis. We then retained the 100 articles (50 for economic development, 50 for cultural values) with the highest annual rate of citations. For each of these highly-cited articles, we exhaustively recorded every cross-national analysis reported in the main text ( $n = 4,308$ ), identifying in each case whether or not the analysis attempted to control for spatial, cultural, or any other form of non-independence between nations (see Methods for detailed search criteria and coding decisions).

The results of our systematic review show that most published articles and

cross-national analyses make no attempt to account for statistical non-independence. Figure 2a plots the proportion of articles that contain at least one cross-national analysis accounting for non-independence. We find that 42% of economic development articles contain at least one attempt to control for non-independence (95% bootstrap confidence interval [0.30 0.54]), while this proportion decreases to only 8% for cultural values articles (95% bCI [0.02 0.16]). Both kinds of article are most likely to use regional fixed effects (e.g. continent fixed effects) to account for non-independence, but some articles also include controls for spatial distance (e.g. latitude) and shared cultural history (e.g. colony status).

Focusing on the full sample of 4,308 analyses, we find that the proportion of individual cross-national analyses accounting for non-independence is even lower (Figure 2b). Across 2,487 cross-national analyses from studies of economic development, only 5% are estimated to control for non-independence (95% credible interval [0.02 0.15]). Similarly, across 1,821 cross-national analyses from studies of cultural values, only 1% are estimated to control for non-independence (95% CI [0.00 0.02]).

Since our systematic review goes back as far as 1993 (Figure 2c), it is possible that our estimates are being biased by earlier studies, and that controls for non-independence have increased over time with methodological advancements and greater awareness of the issue. To test this possibility, we fitted a time trend to the full sample of analyses with a Bayesian multilevel spline model. However, we found that, for both studies of economic development and cultural values, the estimated probability of controlling for non-independence has remained low since 1993 (Figure 2d).

### **Common methods of controlling for non-independence produce inflated false positive rates**

Our systematic review revealed that most cross-national analyses in the literature do not control for spatial or cultural phylogenetic non-independence. When they do, they tend

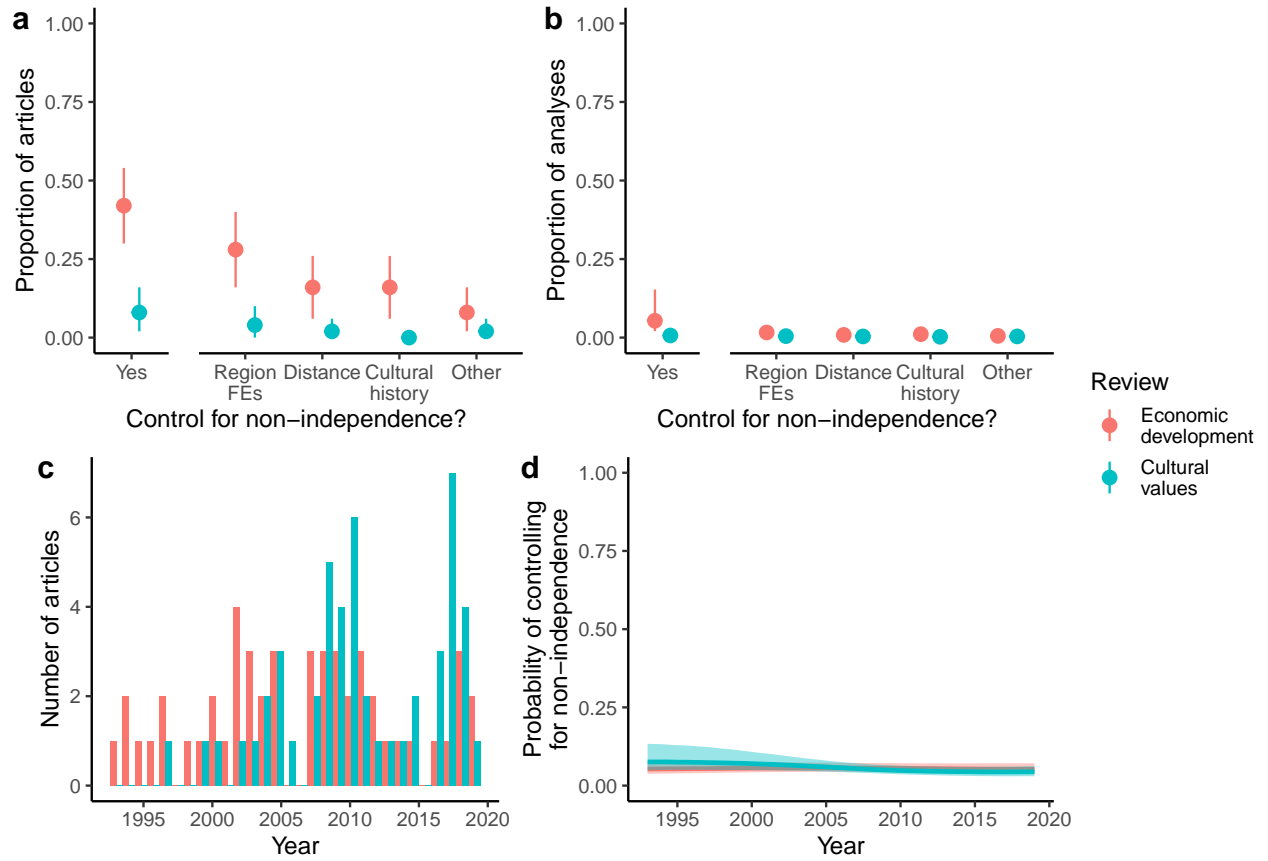

Figure 2. Results from systematic review of 100 highly-cited cross-national studies of economic development (red) and cultural values (blue). (a) Proportion of articles containing at least one analysis accounting for non-independence, overall and split by common methods of controlling for non-independence. Point ranges represent proportions and 95% bootstrap confidence intervals. (b) Adjusted proportion of individual analyses accounting for non-independence, overall and split by method. Point ranges are posterior medians and 95% credible intervals from Bayesian multilevel logistic regressions. (c) Histogram of publication years for studies of economic development and cultural values. (d) Estimated trend over time for the probability of controlling for non-independence. Lines and shaded areas are posterior median regression lines and 50% credible intervals from a Bayesian multilevel spline model. Region FEs = region fixed effects.

to include controls like latitude and regional fixed effects. Do these methods sufficiently account for statistical non-independence?

To compare the efficacy of different methods in the literature, we conducted a simulation study. We simulated national-level datasets ( $n = 236$  nations) with varying degrees of spatial or cultural phylogenetic autocorrelation (i.e. non-independence) for outcome and predictor variables, but with no direct causal relationship between the variables. We then fitted naive regressions without controls to these datasets, as well as regression models with controls for latitude, longitude, and continent fixed effects. Despite not being identified in our systematic review, we also included fixed effects for the language families of the majority-spoken languages in each country, as this control is often used to account for cultural phylogenetic non-independence (e.g.<sup>45</sup>). In addition, we included Conley standard errors, a widely used standard error correction that purportedly accounts for spatial non-independence<sup>46,47</sup>. Finally, we included Bayesian multilevel regressions that explicitly model spatial and/or cultural phylogenetic non-independence by allowing nation random intercepts to covary according to global geographic and/or linguistic proximity matrices (see Supplementary Methods). To model spatial non-independence we included a Gaussian process<sup>48,49</sup> over latitude and longitude values, and to model cultural phylogenetic non-independence we assumed that nation random intercepts were correlated proportional to their linguistic proximity<sup>50</sup>. Across all model types, false positive rates were measured as the proportion of models that estimated a slope with a 95% confidence / credible interval excluding zero (i.e. falsely inferring a relationship when none is present).

Figures 3 and 4 plot the estimated false positive rates from our simulation study, split by different methods and different degrees of spatial or cultural phylogenetic autocorrelation (see Supplementary Figures S2 and S3 for full distributions of effect sizes under strong autocorrelation). For reference, “weak” autocorrelation in our simulation is comparable to the geographic signal for survival values in Figure 1, while “moderate” and “strong” levels of

autocorrelation are comparable to the cultural phylogenetic signal for traditional and survival values, respectively.

Our simulation study revealed that with at least moderate degrees of spatial or cultural phylogenetic autocorrelation for both outcome and predictor variables, naive regression models produce false positive rates above chance levels. This false positive rate increases as the degree of autocorrelation increases. With strong spatial autocorrelation for both outcomes and predictors, false positive rates reach as high as 71%. We find a slightly lower false positive rate under strong cultural phylogenetic autocorrelation, though this false positive rate is still greater than expected by chance (38%).

Common methods in the literature do not reduce these high false positive rates. With strong spatial autocorrelation for both outcome and predictor variables, false positive rates remain above 50% when controlling for latitude, longitude, and language family fixed effects (Figure 3). Applying Conley standard errors also does not reduce false positive rates below 50% under strong spatial autocorrelation, regardless of the distance cutoff. Continent fixed effects are more effective than other frequentist methods, though they continue to produce a false positive rate of 28% under strong spatial autocorrelation. By contrast, Bayesian spatial Gaussian process regression with longitude and latitude values outperforms all other methods. This approach eliminates false positives under moderate spatial autocorrelation, such that the false positive rate is no different from chance, and reduces the false positive rate under strong spatial autocorrelation to 17%. Bayesian models that additionally account for linguistic proximity between nations perform equally well, though models with only linguistic covariance continue to produce false positives.

In our simulation of cultural phylogenetic non-independence, we find that most frequentist methods do not reduce false positive rates (Figure 4). Controls for latitude and longitude, continent fixed effects, and Conley standard errors do little to change false positive rates. Language family fixed effects are slightly more effective than other frequentist

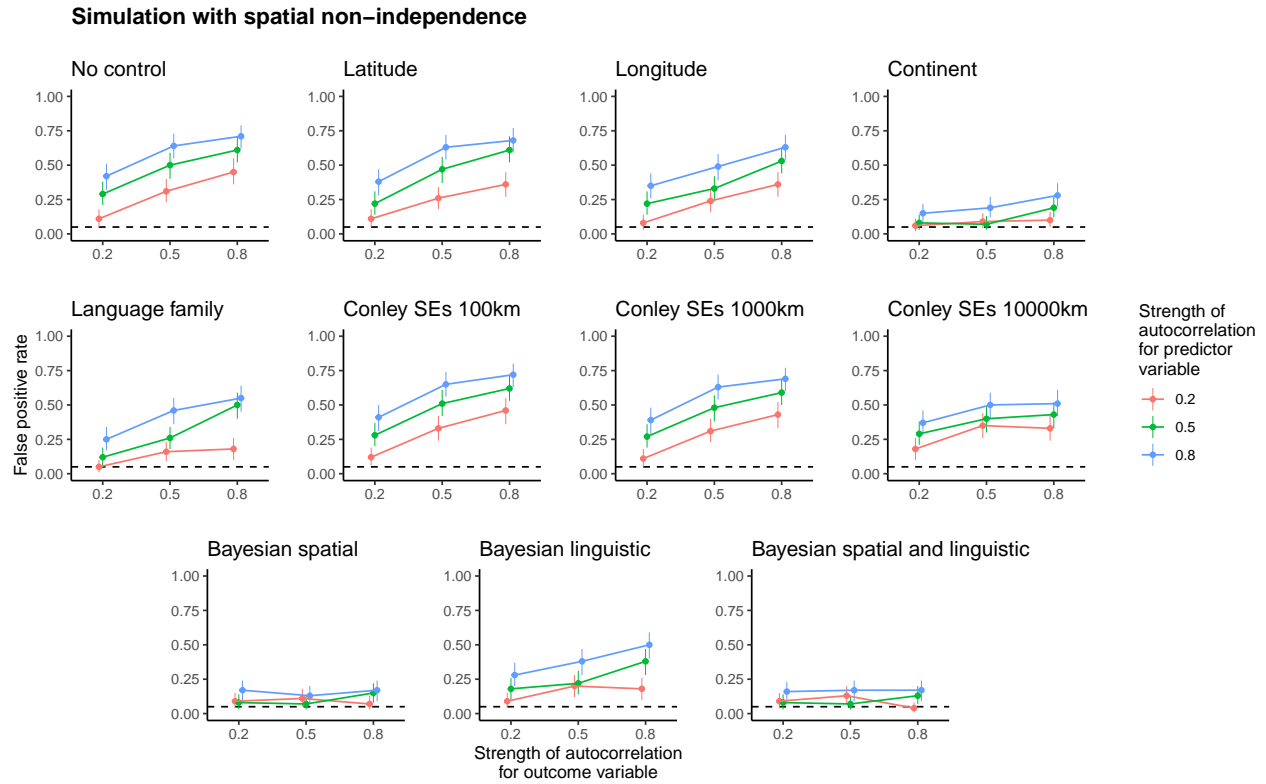

Figure 3. False positive rates for different methods of controlling for spatial non-independence in our simulation study. For simulated outcome and predictor variables, we systematically varied the strength of spatial autocorrelation, from weak (0.2) to moderate (0.5) to strong (0.8). We simulated 100 datasets per parameter combination and fitted different models to each dataset. False positive rates were operationalised as the proportion of models that estimated a slope with a 95% confidence / credible interval excluding zero. Point ranges represent proportions and 95% bootstrap confidence intervals, and dashed lines indicate the 5% false positive rate that is expected due to chance. SEs = standard errors.

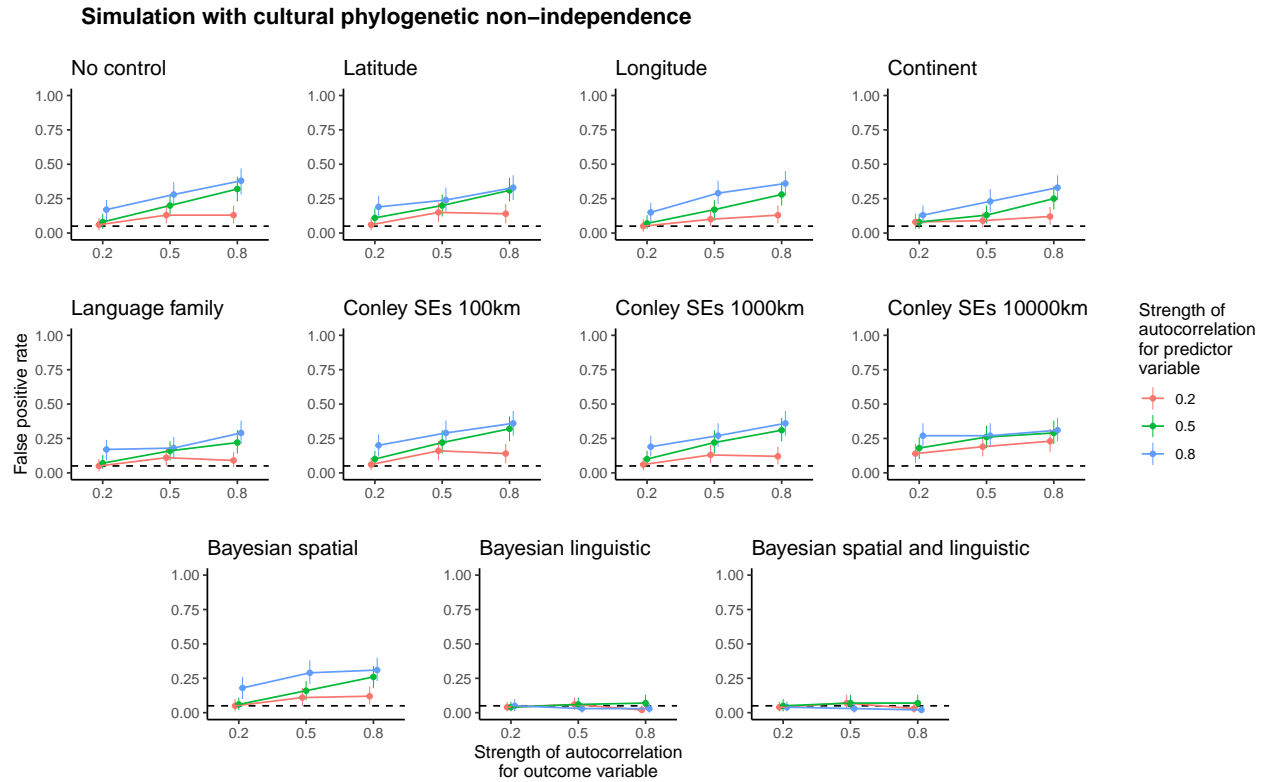

Figure 4. False positive rates for different methods of controlling for cultural phylogenetic non-independence in our simulation study. For simulated outcome and predictor variables, we systematically varied the strength of cultural phylogenetic autocorrelation, from weak (0.2) to moderate (0.5) to strong (0.8). We simulated 100 datasets per parameter combination and fitted different models to each dataset. False positive rates were operationalised as the proportion of models that estimated a slope with a 95% confidence / credible interval excluding zero. Point ranges represent proportions and 95% bootstrap confidence intervals, and dashed lines indicate the 5% false positive rate that is expected due to chance. SEs = standard errors.

methods, though they continue to produce a false positive rate of 29% under strong cultural phylogenetic autocorrelation. By contrast, Bayesian models with random effects covarying according to linguistic proximity completely eliminate false positives across all degrees of cultural phylogenetic autocorrelation. Bayesian models that additionally account for geographic proximity between nations perform equally well, though models with only a spatial Gaussian process continue to produce false positives.

### **Key findings in the literature are not robust to reanalysis with more rigorous methods**

Our systematic review and simulation study have shown that controls for non-independence are rare in cross-national studies of economic development and cultural values, and when studies do attempt to control for non-independence, the methods used continue to produce false positives. This raises the worrying possibility that the cross-national literature in economics and psychology is populated with spurious relationships.

To determine how widespread this issue of spurious cross-national relationships might be, we reanalysed a subset of twelve previous cross-national analyses from our systematic review, sufficiently controlling for spatial and cultural phylogenetic non-independence using global geographic and linguistic proximity matrices. We subsampled six analyses from our economic development review<sup>51–56</sup> and six from our cultural values review<sup>13,14,16,57–59</sup>. Our choice of analyses was constrained by data availability and whether we were able to initially replicate the original finding. We pre-registered our subsample of analyses before running any control models (<https://osf.io/uywx8/>). We controlled for non-independence by including (1) a Gaussian process allowing nation random intercepts to covary according to a geographic proximity matrix, and/or (2) nation random intercepts that covaried according to a linguistic proximity matrix (see Supplementary Methods for full models).

Figure 5 visualises the results of our reanalysis. Cross-national correlation effect sizes tended to reduce when controlling for statistical non-independence between nations, sometimes by as much as half of the original effect size. Overall, after controlling for non-independence, six out of twelve cross-national associations had 95% credible intervals that included zero. For the economic development analyses, four out of six cross-national relationships had 95% credible intervals including zero when controlling for spatial non-independence. For the cultural values analyses, two out of six cross-national relationships had 95% credible intervals including zero when controlling for cultural phylogenetic non-independence. Supplementary Figure S4 shows these cross-national correlations plotted against the raw data.

To understand why some cross-national correlations were attenuated by controls for non-independence while others were robust, we further explored our fitted models for evidence of spatial and cultural autocorrelation. For each outcome variable, our Gaussian process models provided varying estimates of how quickly spatial autocorrelation declined with distance (Supplementary Figure S5). For example, in Skidmore and Toya<sup>56</sup> gross domestic product growth was only moderately spatially autocorrelated at 1000 km distance (posterior median spatial autocorrelation at 1000 km = 0.47, 95% CI [0.06 0.97]), whereas in Inglehart and Baker<sup>16</sup> traditional values were strongly spatially autocorrelated at the same distance (posterior median spatial autocorrelation at 1000 km = 0.96, 95% CI [0.78 0.99]). We also found varying estimates of cultural phylogenetic signal (Supplementary Figure S6), with some outcome variables expressing low signal (e.g. tightness<sup>14</sup>; posterior median = 0.11, 95% CI [0.00 0.82]) and others expressing high signal (e.g. female labour force participation<sup>58</sup>; posterior median = 0.91, 95% CI [0.67 0.99]). Across all analyses, we found that stronger estimates of spatial autocorrelation or cultural phylogenetic signal resulted in a more pronounced reduction in the effect size when controlling for non-independence between nations (Figure 6).

Figure 5. Posterior correlations from our reanalysis of twelve previous cross-national analyses. For each previous cross-national relationship, we plot the posterior slopes from a naive regression (red), a regression controlling for spatial non-independence (green), a regression controlling for cultural phylogenetic non-independence (blue), and a regression controlling for both spatial and cultural phylogenetic non-independence simultaneously (purple). All outcome and predictor variables are standardised. Most analyses are simple bivariate cross-national correlations, but Gelfand et al. (2011) is a partial correlation controlling for log gross national income and Adamczyk and Pitt (2009) is a multilevel model including several covariates. Point ranges represent posterior medians and 95% credible intervals. GDP = gross domestic product. FLFP = female labour force participation.

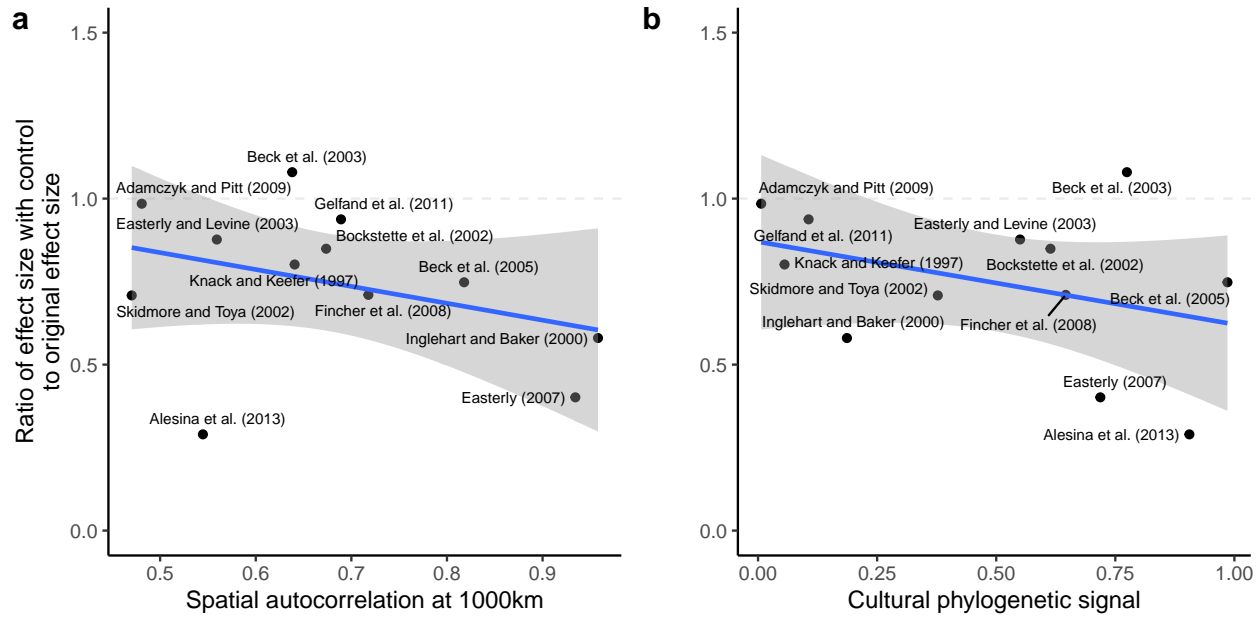

Figure 6. The estimated degree of spatial and cultural phylogenetic non-independence predicts reductions in effect size in our reanalysis. (a) Higher estimated degrees of spatial autocorrelation at 1000 km distance predict more pronounced reductions in effect sizes when controlling for non-independence. (b) Higher estimated levels of cultural phylogenetic signal predict more pronounced reductions in effect sizes when controlling for non-independence. In both panels, the y-axis represents the ratio of the effect size when controlling for spatial and cultural non-independence to the original effect size (from naive regression model), and the x-axis represents posterior median model estimates. Regression lines are plotted with 95% confidence intervals.

## Discussion

In a systematic literature review and simulation, we found that cross-national studies in economics and psychology rarely account for non-independence between nations, and, when they do, the methods they use continue to produce false positives. In a reanalysis of twelve cross-national correlations, we further showed that neglecting to account for non-independence has resulted in spurious relationships in the published literature, with half of the correlations failing to replicate when controlling for spatial or cultural non-independence with more rigorous methods. These findings suggest that cross-national

analyses in economics and psychology should be interpreted with caution until non-independence is sufficiently accounted for.

Our initial analyses add to and clarify existing evidence regarding the non-independence of economic and cultural variation among nations. One previous study suggested that geographic proximity is more important than deep cultural ancestry in explaining the distribution of human development across Eurasian nations, though the authors noted that their small sample of 44 nations and regional focus limited their statistical power<sup>60</sup>. Our global sample of nations revealed strong cultural phylogenetic signal, as well as geographic signal, for the Human Development Index. Another previous study found that similarities in the cultural values of nations are predicted by linguistic, but not geographic, distances between those nations<sup>6</sup>. We find this same result for survival vs. self-expression values, but for traditional vs. secular values we find that both linguistic and geographic proximity are important independent predictors of global variation. These findings emphasise the need to account for both spatial and cultural phylogenetic non-independence in cross-national studies of economic development and cultural values.

Yet our systematic literature review and simulation study revealed that the most commonly used controls for non-independence do not sufficiently deal with the issue. In our simulations, controlling for either latitude or longitude did not reduce false positive rates. This result calls into question controls like distance to the equator to account for non-independence in cross-national regression models, though these controls maybe still be suitable to account for regional or latitudinal variation in ecology, which we did not simulate. High false positive rates persisted with Conley standard errors, which have previously been critiqued for being overly sensitive to arbitrary distance cutoffs<sup>39</sup>. The simulation also confirmed the verbal claim that fixed effects for spatial or cultural groupings (e.g. continent or language family fixed effects) are insufficient because non-independence still remains within groupings<sup>40</sup>. This logic further applies to analyses that control for non-independence

by separately analysing different regions (e.g.<sup>61</sup>). Across all model types in our simulation, the only methods that sufficiently reduced the false positive rate were the Bayesian multilevel regressions that explicitly modelled spatial and cultural phylogenetic autocorrelation, though we did not include other possible controls for non-independence, such as conditional autoregressive models<sup>31</sup> or generalised additive models<sup>62</sup>.

Ours is not the first review to show that studies are misapplying statistical methods in ways that inflate false positive rates. For example, other literature reviews have shown that studies in the social sciences tend to use small sample sizes<sup>63</sup>, treat ordinal data as metric<sup>64</sup>, incorrectly handle missing values<sup>65</sup>, and ignore best practices in meta-analyses<sup>66</sup>. Why do cross-national studies also rarely account for non-independence? At the institutional level, one possibility is that such practices are incentivised *because* they inflate false positive rates, increasing the probability of getting published and promoted<sup>63</sup>. At the individual level, another possibility is that researchers outside of anthropology and ecology are simply not aware of the problem, or believe that the problem does not apply to analyses of nations. Even if researchers appreciate the problem, they might not know of suitable controls or perceive the methods to be too complex.

These institutional- and individual-level barriers can be combatted. First, cross-national replication studies like ours and others<sup>39–43</sup>, combined with the methodological reviews included in Registered Reports<sup>67</sup>, might change incentive structures and encourage researchers to analyse the world’s nations with more rigorous methods. Second, since the issue of non-independence is fundamentally an issue of causal inference (Supplementary Figure S1), more explicit descriptions of causal models could promote controls for non-independence in cross-national research. In our review, economists studying economic development dealt with national-level non-independence more than psychologists studying cultural values, likely because economics studies tend to be lengthy statistical exercises that systematically incorporate or exclude numerous variables in an attempt to infer causation.

332 Third, the recent widespread accessibility of open source statistical software, such as the  
333 programming language Stan<sup>68</sup> and the R package *brms*<sup>69</sup>, should promote the use of more  
334 rigorous methods to control for non-independence. Using *brms*, for example, Bayesian  
335 Gaussian process regression is straightforward to conduct, requiring only longitude and  
336 latitude values for nations.

337       Until such changes are implemented and sufficient controls for non-independence are  
338 the norm, existing cross-national correlations should be interpreted with caution. In our  
339 reanalyses, we found that four out of six cross-national correlations with economic  
340 development variables had 95% credible intervals that included zero when controlling for  
341 spatial non-independence. Three of these analyses were tests of “persistence” hypotheses,  
342 studying the effects of historical and environmental conditions — settler mortality<sup>51</sup>,  
343 wheat-sugar suitability<sup>55</sup>, and natural disaster frequency<sup>56</sup> — on modern developmental  
344 outcomes. A recent reanalysis has also called into question various studies of this ilk<sup>39</sup>. We  
345 also found that two out of six cross-national correlations with cultural values variables had  
346 95% credible intervals that included zero when controlling for cultural phylogenetic  
347 non-independence. It is interesting that the economic development analyses were more  
348 affected by the spatial controls, while the cultural values analyses were more affected by the  
349 cultural phylogenetic controls. This highlights that certain kinds of non-independence will be  
350 more important depending on the particular national-level outcome and predictor variables  
351 of interest.

352       We do not wish to dissuade researchers from conducting cross-national studies. On the  
353 contrary, such work promises to deepen our understanding of the causes and consequences of  
354 economic development and cultural values around the world. Moreover, cross-national  
355 studies allow social scientists to broaden their scope of study beyond Western populations<sup>7</sup>,  
356 providing the representative samples necessary to test evolutionary and socio-ecological  
357 theories of human behaviour<sup>8,70</sup>. But in order to minimise spurious relationships in global

datasets, we urge researchers to control for spatial and cultural phylogenetic non-independence when reporting cross-national correlations. Nations are not independent, and our statistical models must reflect this.

## Methods

### Geographic and cultural phylogenetic signal

To estimate the degree of spatial and cultural phylogenetic non-independence in economic development and cultural values, we calculated geographic and cultural phylogenetic signal for global measures of development and values. Our measure of economic development was the Human Development Index<sup>44</sup>. We retrieved a longitudinal dataset capturing human development for 189 nations since 1990 ( $n = 1,512$ ; <https://hdr.undp.org/en/content/download-data>). Our measures of cultural values were traditional vs. secular values and survival vs. self-expression values from the World Values Survey<sup>16</sup>. We downloaded the full Integrated Values Survey, which included all waves from the World Values Survey and the European Values Survey, and computed the two dimensions of cultural values following procedures from previous research<sup>16</sup>. This longitudinal dataset captures values and attitudes for 116 nations since 1981 ( $n = 645,249$ ; <https://www.worldvaluessurvey.org/WVSEVStrend.jsp>).

To calculate geographic and cultural phylogenetic signal, we created two proximity matrices for 269 of the world's nations: a geographic proximity matrix and a linguistic proximity matrix. Geographic proximity was converted from logged geodesic distances between nation capital cities. Linguistic proximity was calculated as the cultural proximity between all languages spoken within nations, weighted by speaker percentages (see Supplementary Methods). We included these matrices in Bayesian multilevel models, allowing nation random intercepts to covary according to both geographic and linguistic proximity simultaneously. These models were fitted with the R package *brms*<sup>69</sup> and converged normally ( $\hat{R} < 1.1$ ). Estimates of geographic and cultural phylogenetic signal were

computed as the proportion of national-level variance in these models explained by geographic and linguistic proximity matrices.

### Systematic literature review

We exported two searches from Web of Science (<https://www.webofknowledge.com/>) on 27<sup>th</sup> September 2021, restricting our searches to articles published between 1900 and 2018. The first search was for the terms “economic development” AND (“cross-national” OR “cross-cultural” OR “cross-country”), which returned 965 articles. The second search was for the terms “values” AND (“cross-national” OR “cross-cultural” OR “cross-country”), which returned 6806 articles. Once exported, we ordered the articles by descending number of citations per year since initial publication, using citation counts reported by Web of Science.

We then systematically coded each article, in order, for inclusion in our review. Articles were only included if: (1) they were judged to be relevant to economic development or cultural values; (2) they were an original empirical research article; and (3) they contained at least one analysis with national-level outcome or predictor variables. We stopped when we had included 50 articles for the economic development review and 50 articles for the cultural values review.

Within each included article, we exhaustively coded every individual cross-national analysis reported in the main text. We coded mainly correlation or regression analyses, and explicitly excluded meta-analyses, factor analyses, measurement invariance analyses, multidimensional scaling analyses, hierarchical clustering analyses, multiverse analyses, and scale development / validation analyses. We also excluded analyses that compared only two, three, four, five, or six nations. For each included analysis, we recorded the year, outcome variable, all predictor variables, test statistic, p-value, number of nations, number of data points, model type, if the data were available, and whether and how the analysis attempted to control for non-independence.

We coded common attempts to control for non-independence between nations. These included: (1) any higher-level control variables for spatial regional groupings (e.g. continent fixed effects); (2) any geographic distance control variables (e.g. distance between capital cities, distance from equator, latitude); (3) any control variables capturing shared cultural history (e.g. former colony, legal origin fixed effects, linguistic history, cultural influence); and (4) any other control variables, tests, or approaches that were deemed as attempts to control for non-independence (e.g. eigenvector filtering<sup>71</sup>, controls for trade-weightings between countries, cross-sectional dependence tests<sup>72</sup>, separate analyses for subsets of countries). These were coded by the first author.

Once we had compiled our review database, we calculated the proportion of articles attempting to control for non-independence at least once. We also calculated the proportion of articles employing the different types of control listed above at least once: regional fixed effects, distance, shared cultural history, or other. For these proportions, we calculated 95% bootstrap confidence intervals with 1000 bootstrap iterations.

For individual analyses, we dealt with the nested nature of the data (analyses nested within articles) by fitting Bayesian multilevel logistic regression models with review type (economic development vs. cultural values) as the sole fixed effect and random intercepts for articles. We fitted these models separately for overall attempts to control for non-independence and split by method type. We report the adjusted proportions with 95% credible intervals. To test for a trend over time, we also fitted a Bayesian multilevel logistic regression with a multigroup spline for year of publication and random intercepts for articles. Bayesian models were fitted with the *brms* R package<sup>69</sup>. Our priors were informed by prior predictive checks, and all models converged normally ( $\hat{R} < 1.1$ ).

## 432 Simulations

433 We simulated data for 236 nations with varying degrees of spatial or cultural  
 434 phylogenetic signal for outcome  $y$  and predictor  $x$  using the following generative model:

$$y = \alpha_y + \epsilon_y$$

$$x = \alpha_x + \epsilon_x$$

$$\alpha_y \sim \mathcal{N}(0, \sqrt{\lambda} \cdot \Sigma)$$

$$\alpha_x \sim \mathcal{N}(0, \sqrt{\rho} \cdot \Sigma)$$

$$\epsilon_y \sim \mathcal{N}(0, \sqrt{1 - \lambda})$$

$$\epsilon_x \sim \mathcal{N}(0, \sqrt{1 - \rho})$$

435 where  $\Sigma$  is a correlation matrix proportional to either geographic or linguistic  
 436 proximities between nations, and  $\lambda$  and  $\rho$  are autocorrelation parameters that represent the  
 437 expected spatial or cultural phylogenetic signal for outcome and predictor variables,  
 438 respectively. Importantly, in this simulation, we know that there is no direct causal  
 439 relationship between  $y$  and  $x$  because we simulate the variables independently. Instead, any  
 440 relationship between the two variables is merely the result of autocorrelation.

441 We set the autocorrelation parameters to either 0.2 (weak), 0.5 (moderate), or 0.8  
 442 (strong). We simulated 100 datasets for each parameter combination, resulting in 900  
 443 datasets. Each dataset had 236 rows representing different nations, with the following  
 444 associated data for each nation: latitude, longitude, continent (Africa, Asia, Europe, North  
 445 America, Oceania, or South America), and language family of the nation's majority spoken  
 446 language (Afro-Asiatic, Atlantic-Congo, Austroasiatic, Austronesian, Eskimo-Aleut,  
 447 Indo-European, Japonic, Kartvelian, Koreanic, Mande, Mongolic-Khitan, Nilotic, Nuclear  
 448 Trans New Guinea, Sino-Tibetan, Tai-Kadai, Tupian, Turkic, or Uralic).

With the resulting simulated datasets, we standardised outcome and predictor variables and fitted eleven different models: (1) naive regression without controls, (2) regression with latitude control, (3) regression with longitude control, (4) regression with continent fixed effects, (5) regression with language family fixed effects, (6) regression employing Conley standard errors with 100 km cutoff, (7) regression employing Conley standard errors with 1,000 km cutoff, (8) regression employing Conley standard errors with 10,000 km cutoff, (9) Bayesian regression including a Gaussian process over latitudes and longitudes, (10) Bayesian regression including random intercepts covarying according to linguistic proximity, and (11) Bayesian regression including both a Gaussian process over latitudes and longitudes and random intercepts covarying according to linguistic proximity.

Models employing Conley standard errors required latitude and longitude values, and the cutoffs implied the distance beyond which autocorrelation is assumed to be zero. These models were fitted using the *conleyreg* R package<sup>73</sup>. Bayesian models were fitted using the *brms* R package<sup>69</sup>. Our choice of priors was based on prior predictive simulation. All models converged normally ( $\hat{R} < 1.1$ ). Across all model types and parameter combinations, we calculated the false positive rate as the proportion of models that estimated slopes with a 95% confidence / credible interval excluding zero. We calculated 95% bootstrap confidence intervals for these false positive rates with 1000 bootstrap iterations.

## Reanalyses

We searched the individual analyses from our systematic review for cross-national correlations with available data. We included only analyses for which we were able to replicate the original result (i.e. find a cross-national correlation with the same sign and roughly the same effect size). We restricted our search to one analysis per article, and aimed for an even number of analyses for both economic development and cultural values studies. We also ensured that at least one analysis was a multilevel model, with multiple observations per nation.

The twelve analyses that we settled on<sup>13,14,16,51–59</sup> were mostly bivariate cross-national correlations, except for two. One analysis<sup>14</sup> additionally controlled for log gross national income, and another analysis<sup>56</sup> is a multilevel model including random intercepts for nations and several individual-level and national-level covariates (see Model 5 in original paper). Before running any additional models, we pre-registered these twelve analyses on the Open Science Framework on 25<sup>th</sup> January 2022 (<https://osf.io/uywx8/>).

For each individual analysis, we conducted four models: (1) a naive regression replicating the original finding, (2) a regression including a Gaussian process allowing nation random intercepts to covary according to a geographic proximity matrix from latitude and longitude values, (3) a regression including nation random intercepts that covaried according to a linguistic proximity matrix, and (4) a regression including both a geographic Gaussian process and nation random intercepts with linguistic covariance. See Supplementary Methods for full models.

We fitted these models using the *brms* R package<sup>69</sup>. Our choice of priors was based on prior predictive simulation. All models converged normally ( $\hat{R} < 1.1$ ), though for some models we resorted to using approximate Gaussian processes<sup>74</sup> to reach convergence.

## Reproducibility

All data and code are accesible at our Open Science Framework repository (<https://osf.io/uywx8/>). We used the *targets* R package<sup>75</sup> to create a reproducible data analysis pipeline and the *papaja* R package<sup>76</sup> to reproducibly generate the manuscript.

## Supplementary Material

### Supplementary Methods

**Calculating global geographic and linguistic proximity matrices.** Geographic distance between two nations was calculated as the logged geodesic distance between country capital cities (data from the R package *maps*<sup>77</sup>) using the R package *geosphere*<sup>78</sup>. The geographic proximity matrix was computed as one minus the log geographic distance matrix scaled between 0 and 1.

Linguistic proximity between two nations was calculated as the cultural proximity between all languages spoken within those nations, weighted by speaker percentages. We acquired cultural proximity data by combining the language family trees provided by Glottolog v3.0<sup>79</sup> into one global language tree (undated and unresolved). We calculated cultural proximity  $s$  between two languages  $j$  and  $k$  as the distance (in number of nodes traversed) of their most recent common ancestor  $i$  to the root of the tree, through the formula:

$$s_{jk} = \frac{n_r - n_i}{n_r}$$

where  $n_r$  is the maximum path length (in number of nodes traversed) leading to the pan-human root  $r$ , and  $n_i$  is the maximum path length leading to node  $i$ . We then combined these proximities with speaker data from Ethnologue 21<sup>80</sup> and compared every language spoken within those nations by at least 1 permille of the population, weighted by speaker percentages, through the formula:

$$w_{lm} = \sum \sum p_{lj} p_{mk} s_{jk}$$

where  $p_{lj}$  is the percentage of the population in nation  $l$  speaking language  $j$ ,  $p_{mk}$  is the percentage of the population in nation  $m$  speaking language  $k$ , and  $s_{jk}$  is the proximity measure between languages  $j$  and  $k$ <sup>81</sup>. The resulting linguistic proximity matrix was also scaled between 0 and 1 before analysis.

**Bayesian models for reanalysis.** We provide model formulae for our reanalyses of cross-national correlations, for a general bivariate case with standardised outcome  $Y$  and predictor  $X$  variables. In the naive regression model without controls for non-independence:

$$Y_i \sim \text{Normal}(\mu_i, \sigma)$$

$$\mu_i = \alpha + \beta X_i$$

$$\alpha \sim \text{Normal}(0, 0.4)$$

$$\beta \sim \text{Normal}(0, 0.4)$$

$$\sigma \sim \text{Exponential}(5)$$

The priors in this model were arrived at by prior predictive checks, with wider priors making predictions beyond the scale of standardised outcome variables and narrower priors being too informative.

To control for spatial non-independence, we add a Gaussian process to this model and feed it a scaled geographic distance matrix  $D$  based on Euclidean distances between latitude and longitude coordinates. This distance matrix is computed internally by the R package *brms*<sup>69</sup>. The Gaussian process uses an exponentiated quadratic covariance kernel, the only covariance kernel currently supported by *brms*. The model formula is:

$$\begin{aligned}
 Y_i &\sim \text{Normal}(\mu_i, \sigma) \\
 \mu_i &= \alpha + \kappa_{\text{NATION}[i]} + \beta X_i \\
 \begin{pmatrix} \kappa_1 \\ \kappa_2 \\ \kappa_3 \\ \dots \\ \kappa_n \end{pmatrix} &\sim \text{MVNormal} \left( \begin{pmatrix} 0 \\ 0 \\ 0 \\ \dots \\ 0 \end{pmatrix}, \mathbf{K} \right) \\
 \mathbf{K}_{ij} &= sdgp^2 \exp(-D_{ij}^2 / (2lscale^2)) \\
 \alpha &\sim \text{Normal}(0, 0.4) \\
 \beta &\sim \text{Normal}(0, 0.4) \\
 \sigma &\sim \text{Exponential}(5) \\
 sdgp &\sim \text{Exponential}(5) \\
 lscale &\sim \text{InverseGamma}(?, ?)
 \end{aligned}$$

where  $n$  is the number of nations, and  $D_{ij}^2$  reflects the squared Euclidean distances between latitude and longitude coordinates for the  $i$ -th and  $j$ -th nations. Notice that the inverse gamma prior on  $lscale$  is left undetermined. This is because the *brms* package intelligently tunes the prior for this parameter based on the covariates of the Gaussian process (see [https://betanalpha.github.io/assets/case\\_studies/gp\\_part3/part3.html](https://betanalpha.github.io/assets/case_studies/gp_part3/part3.html)).

709        To control for cultural phylogenetic non-independence, we manually specify the  
 710 covariance structure for nation random intercepts using a pre-computed linguistic proximity  
 711 matrix  $L$  (see previous section). The covariance between two nations is assumed to be  
 712 linearly proportional to the linguistic proximity between those nations. This assumption is  
 713 justified if we assume that cultural traits evolve via Brownian motion along a language  
 714 phylogeny. The non-centered parameterisation of this model is:

$$Y_i \sim \text{Normal}(\mu_i, \sigma)$$

$$\mu_i = \alpha + z_{\text{NATION}[i]} \sigma_\alpha L + \beta X_i$$

$$\alpha \sim \text{Normal}(0, 0.4)$$

$$\beta \sim \text{Normal}(0, 0.4)$$

$$z_j \sim \text{Normal}(0, 1)$$

$$\sigma_\alpha \sim \text{Exponential}(5)$$

$$\sigma \sim \text{Exponential}(5)$$

715 Finally, we can control for spatial and cultural phylogenetic non-independence  
 716 simultaneously by including both a Gaussian process over latitude and longitude coordinates  
 717 *and* nation random intercepts that covary according to linguistic proximity. The resulting  
 718 model is as follows:

$$\begin{aligned}
 Y_i &\sim \text{Normal}(\mu_i, \sigma) \\
 \mu_i &= \alpha + \kappa_{\text{NATION}[i]} + z_{\text{NATION}[i]} \sigma_\alpha L + \beta X_i \\
 \begin{pmatrix} \kappa_1 \\ \kappa_2 \\ \kappa_3 \\ \dots \\ \kappa_n \end{pmatrix} &\sim \text{MVNormal} \left( \begin{pmatrix} 0 \\ 0 \\ 0 \\ \dots \\ 0 \end{pmatrix}, \mathbf{K} \right) \\
 \mathbf{K}_{ij} &= sdgp^2 \exp(-D_{ij}^2 / (2lscale^2)) \\
 \alpha &\sim \text{Normal}(0, 0.4) \\
 \beta &\sim \text{Normal}(0, 0.4) \\
 z_j &\sim \text{Normal}(0, 1) \\
 \sigma_\alpha &\sim \text{Exponential}(5) \\
 \sigma &\sim \text{Exponential}(5) \\
 sdgp &\sim \text{Exponential}(5) \\
 lscale &\sim \text{InverseGamma}(?, ?)
 \end{aligned}$$

## Supplementary Results

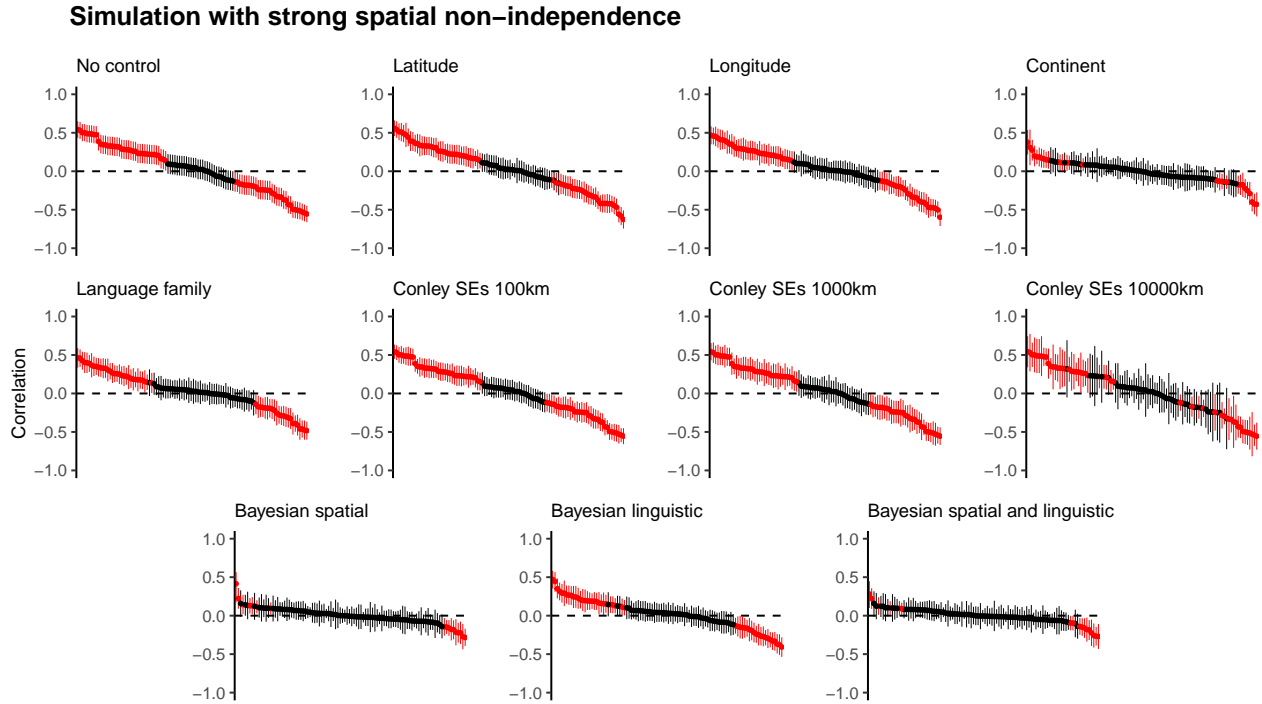

### Geographic and cultural phylogenetic signal estimates for Human

**Development Index and Inglehart's value dimensions.** Controlling for shared cultural ancestry, the proportion of national-level variance explained by spatial proximity was 0.37 for the Human Development Index (95% credible interval [0.19 0.60];  $\text{BF}_{\neq 0} > 100$ ), 0.43 for traditional values (95% CI [0.19 0.73];  $\text{BF}_{\neq 0} > 100$ ), and 0.18 for survival values (95% CI [0.01 0.44];  $\text{BF}_{\neq 0} = 1.77$ ). Controlling for spatial proximity, the proportion of variance explained by shared cultural ancestry was 0.61 for the Human Development Index (95% CI [0.39 0.80];  $\text{BF}_{\neq 0} > 100$ ), 0.55 for traditional values (95% CI [0.26 0.79];  $\text{BF}_{\neq 0} > 100$ ), and 0.79 for survival values (95% CI [0.54 0.96];  $\text{BF}_{\neq 0} > 100$ ).

729 **Supplementary Figures**

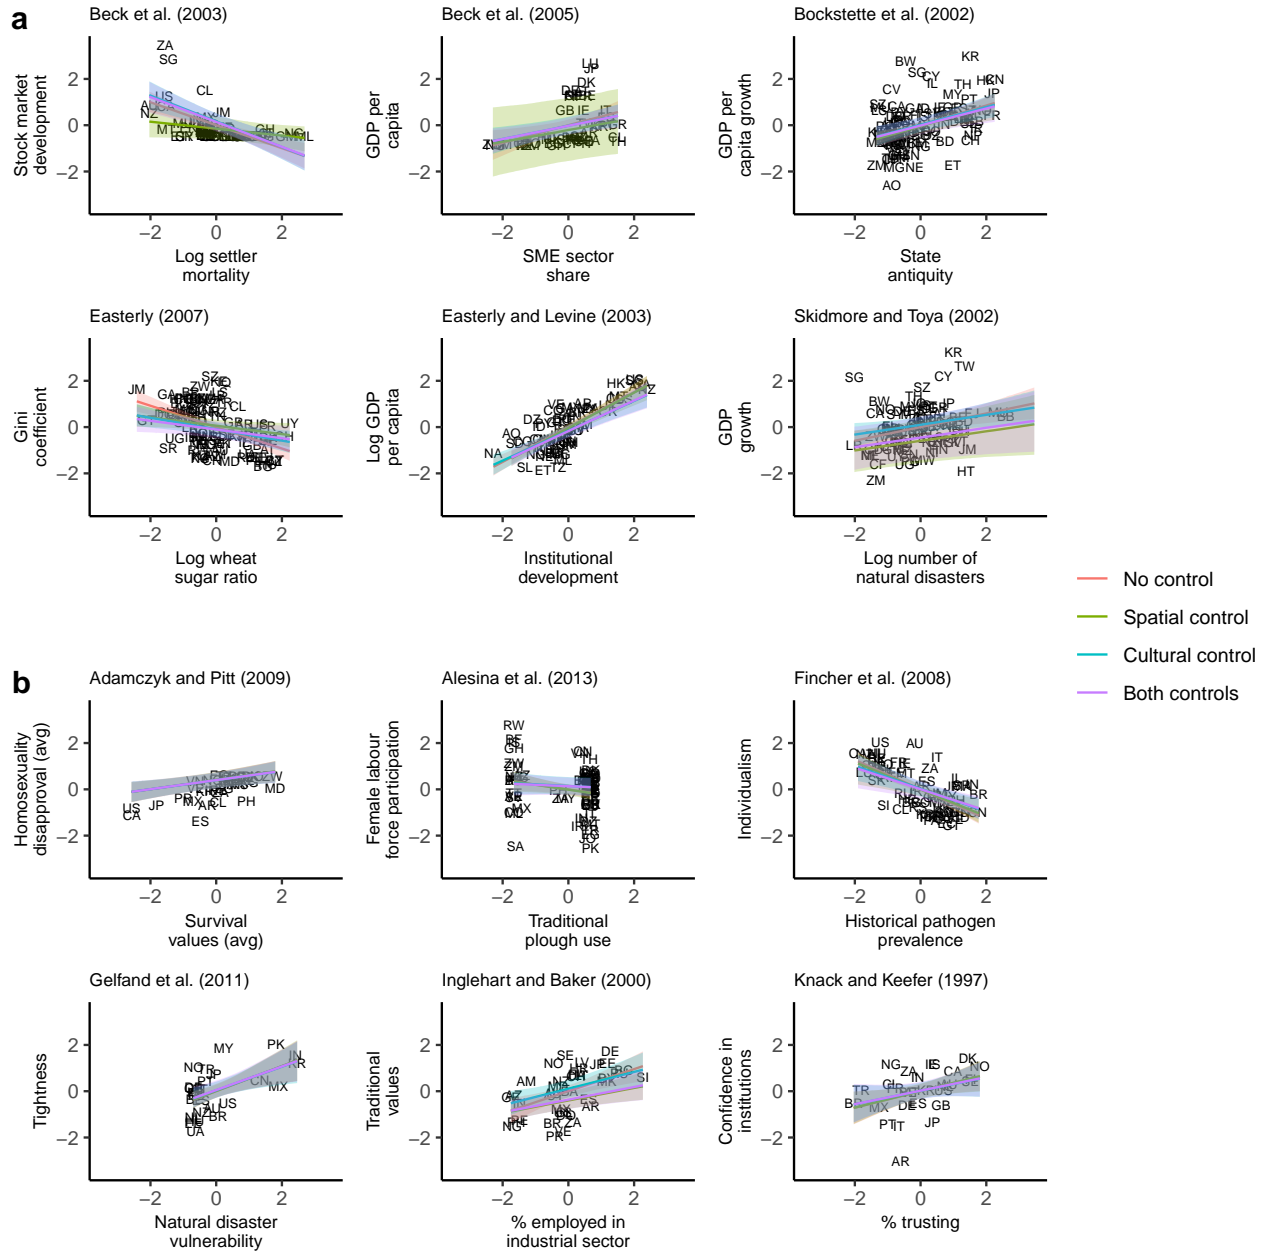

*Supplementary Figure S1. A causal directed acyclic graph of spatial and cultural phylogenetic non-independence in cross-national studies.* We are interested in estimating the direct effect of national-level exposure  $X$  on national-level outcome  $Y$ . But these variables are confounded by their common unobserved cause  $U$ .  $U$  is a stand-in for shared environmental, ecological, and geographic causes (e.g. climate, biodiversity, physical topography) and cultural and institutional causes (e.g. cultural norms, political systems). In this causal model, we need to condition on  $U$  to estimate the direct path from  $X$  to  $Y$ , but we cannot since it is unobserved. However, geographic  $G$  and linguistic  $L$  relationships between societies influence  $U$ , since changing a nation's spatial distance to or shared cultural ancestry with other nations will change its environmental and cultural traits. We can thus use  $G$  and  $L$  to model the covariation between  $X$  and  $Y$  induced by  $U$ . Failing to do this and simply estimating the bivariate correlation between  $X$  and  $Y$  will produce spurious relationships and residuals that are spatially and culturally non-independent around the world.

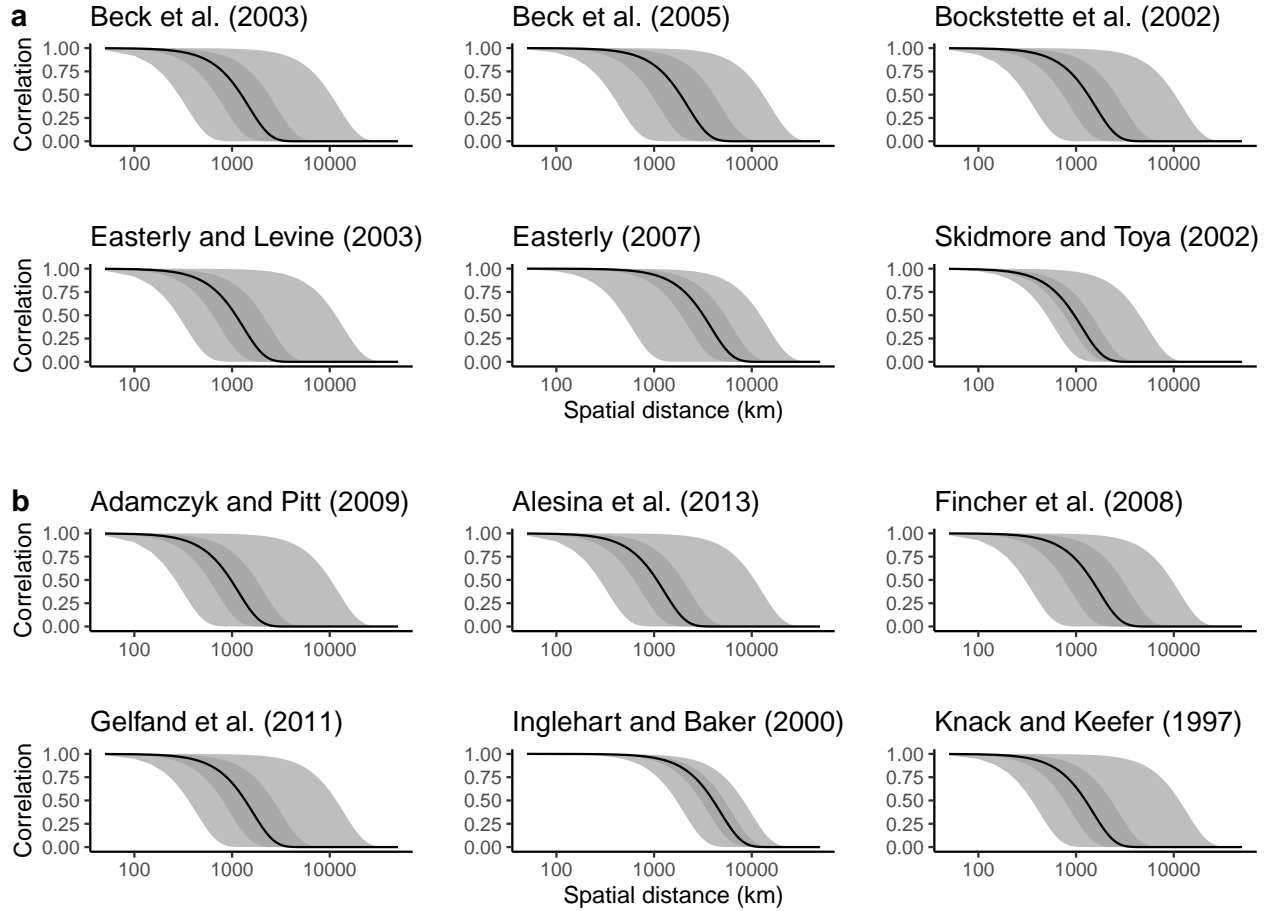

*Supplementary Figure S2. Distribution of cross-national correlations from simulation study under strong spatial autocorrelation.* In these simulations, the strength of spatial autocorrelation is set to 0.8 for both outcome and predictor variables. For frequentist regression models, point ranges represent correlation estimates and 95% confidence intervals. For Bayesian regression models, point ranges represent posterior means and 95% credible intervals. Correlations are ordered by effect size independently in each panel. Red point ranges indicate that the slope is “significant” (i.e. the 95% confidence / credible interval excludes zero). Black point ranges indicate that the slope is “not significant”.

*Supplementary Figure S3. Distribution of cross-national correlations from simulation study under strong cultural phylogenetic autocorrelation.* In these simulations, the strength of cultural phylogenetic autocorrelation is set to 0.8 for both outcome and predictor variables. For frequentist regression models, point ranges represent correlation estimates and 95% confidence intervals. For Bayesian regression models, point ranges represent posterior means and 95% credible intervals. Correlations are ordered by effect size independently in each panel. Red point ranges indicate that the slope is “significant” (i.e. the 95% confidence / credible interval excludes zero). Black point ranges indicate that the slope is “not significant”.

*Supplementary Figure S4. Reanalysis models fitted to raw data, for economic development (a) and cultural values (b) studies. Data points are labelled using ISO 3166-1 alpha-2 letter country codes. In all reanalyses, outcome and predictor variables are standardised, making regression slopes comparable to Pearson's correlation coefficients. Lines and shaded areas represent posterior median regression lines and 95% credible intervals. For models with covariates (Adamczyk and Pitt 2009; Gelfand et al. 2011), marginal effects are presented holding all covariates at zero or their reference categories.*

*Supplementary Figure S5. Posterior estimates of Gaussian process functions mapping spatial autocorrelation onto geographic distance from our reanalyses of economic development (a) and cultural values (b) studies. Estimates are from models additionally controlling for cultural phylogenetic non-independence. The y-axis represents the amount of spatial autocorrelation between data points with increasing distance between those points on the x-axis (logged distance in kilometres). Lines and shaded areas represent median posterior spatial autocorrelation functions and 50% and 95% credible intervals.*

*Supplementary Figure S6. Posterior estimates of cultural phylogenetic signal from our reanalyses.* Estimates are from models additionally controlling for spatial non-independence. Cultural phylogenetic signal is operationalised as the proportion of national-level variance explained by linguistic proximity between nations. Ridges are full posterior distributions, and points are posterior medians, and lines represent 50% and 95% credible intervals.
